Topics in this section

- Skeleton network-based approaches (Oct 16th, 2018)
- Input/Output Hidden Markov Models
- Multi-task learning of graphs

Goals for today

- Overview of different models to capture contextspecificity/dynamics
- Skeleton network based approaches

What do we mean by context?

- We will define context broadly
- Context can be time, developmental stage, tissue, cell type, organ, disease, strains/individuals, species

Different cell types

Different individuals

Different species

Network dynamics and context specificity

- What does modeling "dynamics" mean?
 - The activity of nodes change over time and we want to model how this happens
 - The network (structure or parameters) changes with time
 - Structure can change due to changes at the node or edge level
- What models can be used for capturing dynamics in networks?
- How do these models capture dynamics?
 - Node level
 - Edge level

Strategies for capturing dynamics in networks

- Ordinary Differential Equation (ODE) based approaches
- Skeleton network-based approaches
- Dynamic Bayesian Networks and non-stationary extensions
- Input/Output Hidden Markov Models
- Multi-task learning approaches
- Dynamic networks with temporal transition of edges/Time varying networks

ODE based models in networks

- Assume we are modeling a gene regulatory network
- Let x_i denote the expression level of the i^{th} gene
- ODE for the change in expression of i^{th} gene is Expression level of regulator p $\frac{dx_i}{dt} = -\alpha_i x_i + \sum_{p \in P_i \leftarrow \text{Regulators of } i^{th} \text{ gene}} \beta_{i,p} x_p$
- This is often approximated by a finite difference approximation

$$\frac{x_i(t+1) - x_i(t)}{t_{k+1} - t_k} = -\alpha_i x_i(t_k) + \sum_{p \in P_i} \beta_{i,p} x_p(t_k)$$

Greenfield et al., Bioinformatics 2013

Skeleton network-based approaches

- Assume that we have background/skeleton network that defines the universe of possible edges
- The network changes because node activity levels change

Kim et al. 2013, Briefings in Bioinformatics

Dynamic Bayesian networks (DBNs)

- Suppose we have a time course of node activity levels
- We assume that the activity levels at time t+1 depends upon t
 - But this does not change with t
- DBNs can be used to model how the system evolves over time
 - We may have a different network at the first time point

Non-stationary Dynamic Bayesian Networks (nsDBNs)

- The standard DBN assumes that the dependency between the previous time point (*t*-1) and the current time point (t) is the same
 - This is called the stationarity assumption in DBNs
- Non-stationary DBNs are DBNs where this assumption is relaxed
 - Introduced by Robinson and Hartemink 2010
 - Depending upon the time-window/epoch we might have a different dependency structure

Non-stationary Dynamic Bayesian Networks

- Suppose we have three time windows
- nsDBNs require us to define the dependency structure in each time window

Non-stationary Dynamic Bayesian Networks continued

• For *m* epochs, we would like to find *G*₁,.., *G*_{*m*} by optimizing their posterior distribution

$$P(G_1, .., G_m | D) \propto P(D | G_1, .., G_m)$$
$$P(G_1, .., G_m)$$

Prior over *m* graphs; can be used to incorporate our prior knowledge of how the graphs transition

$$P(G_1, .., G_m | D) \propto P(D | G_1, .., G_m)$$
$$P(G_1, \Delta g_1, \Delta g_2, .., \Delta g_{m-1})$$

Time-varying Networks

- The network changes between time at the node and edge levels
- Example approaches
 - TESLA (Ahmed & Xing, PNAS 2009)
 - KELLER (Song et al., Bioinformatics 2009)
- TESLA
 - Based on temporal Exponential Random Graph Models
 - Assumes binary node values
 - works by imposing a regularization term to make the graphs change smoothly over time
 - estimates the graph structure by solving a set of local regularized logistic regression problems

Applying TESLA to US senators of the 109th congress

Each node is a senator. The networks were inferred using voting records of 642 bills. Votes are binary states at each time point. Voting records were grouped into 12 epochs, each epoch comprising 2 months.

Goals for today

- Overview of different models to capture contextspecificity/dynamics
- Skeleton network based approaches

Skeleton network-based approaches

- Given
 - A fixed network of nodes (genes, proteins, metabolites)
 - Activity levels of network nodes in a set of contexts (e.g. tissues, time points)
- Do
 - Find subset of edges that are active in each context

Kim et al. 2013, Briefings in Bioinformatics Transitional networks

Active subnetworks: A skeleton-network based approach

- Active subnetworks: A subnetwork that exhibits an unexpectedly high level of expression change
 - "Discovering regulatory and signalling circuits in molecular interaction networks". By Trey Ideker, Owen Ozier, Benno Schwikowski, Andrew Siegel. Bioinformatics. 2002;18 Suppl 1:S233-40.
- Enables us to gain a better understanding of how expression is controlled at the network level
- Enables us to link gene expression changes to higher order interactions

Active subnetworks key idea

- Given
 - Network structure and expression data (actually P-values specifying the significance of expression of a gene)
- Find
 - Subnetwork that is differentially active
- Active network identification requires solving these tasks:
 - Define a score of subnetwork activity
 - One or multiple conditions
 - Search for high-scoring subnetworks

Defining the score for subnetwork activity

- The score is going to be a z-score
 - The number of standard deviations from the mean.
- Need to compute a z-score associated with each subnetwork A
- Start with assessing differential expression of each gene
 - P-value for significance of expression p_i
- Convert P-value to gene level z-score z_i

$$z_i = \Phi^{-1}(1 - p_i)$$

Inverse normal CDF

Aggregate z-scores for all genes in subnetwork A

$$z_A = \frac{1}{\sqrt{k}} \Sigma_{i \in A} z_i$$

Calibrate this against a background distribution $z_A - \mu_k$

 $s_A =$

Estimated from randomly sampling gene sets of size k

Example of a score of subnetwork activity

Extending the scoring criteria to multiple conditions

- Suppose we had *m* different conditions
- Given a subnetwork A, compute a set of z-scores for A in all m conditions

$$(z_{A(1)}, z_{A(2)}, \cdots, z_{A(m)})$$

- Score of a subnetwork for multiple conditions is proportional to the probability that the subnetwork is active in at least j of the m conditions
- ϕ is the CDF of the normal distribution
- The probability of subgraph to have a score of at most $Z_{A(i)}$,

$$\phi(Z_{A(j)}) = P(s_A \le Z_{A(j)})$$

Extending the scoring criteria to multiple conditions

• Hence, the probability that any single condition has score at least $Z_{A(j)}$ $P = 1 - \phi(Z_{A(j)})$

$$P_z = 1 - \phi(Z_{A(j)})$$

- Probability that at least *j* of *m* conditions has score at least $Z_{A(j)}$ $p_{A(j)} = \sum_{h=j}^{m} {m \choose h} P_z^h (1 - P_z)^{m-h}$
- This is equivalent to a p-value for $z_{A(j)}$

$$r_{A(j)} = \phi^{-1}(1 - p_{A(j)})$$

 $r_A^{\max} = \max_i(r_{A(i)})$

- Score associated with the *j*th subset of conditions
- Score associated with best subset

Overview of scoring criteria for multiple conditions

- (i) Score for each condition
- (ii) Sorted scores
- (iii) Z-score calculation for the j^{th} subset

Active subnetwork finding algorithm

- Given a subnetwork, we now have a way to score its activity in one or more conditions
- How do we find such a subnetwork?
- We need to search in the space of subnetworks, score each subnetwork and select the most active ones

Simulated annealing to find active subnetworks

- Finding the maximal scoring subnetwork is computationally intractable
- Apply simulated annealing to find a close approximation to the global optimum
- Simulated annealing
 - A heuristic search approach to find a good approximation to the global optimum
 - Enables one to take non-optimal steps to avoid being too greedy

Simulated annealing

- Requires a "Temperature" schedule that starts from a high value and gradually "cools" down
 - At high temperatures (beginning), it will accept more nonoptimal moves
 - At low temperatures, the probability of accepting nonoptimal moves is smaller
- Let e and e' be the scores of the current and new moves
- Probability of accepting e' is

$$P(e, e', T_i) = \begin{cases} 1, \text{ if } e < e' \\ \exp(\frac{e - e'}{T_i}) \end{cases}$$

Simulated Annealing example

https://www.youtube.com/watch?v=iaq_Fpr4KZc

Algorithm sketch to find a high scoring subnetwork

- **Input**: Graph G=(V,E), Number of iterations N, Temperature function T_i which decreases geometrically from T_{start} to T_{end}
- **Output**: A subgraph G_w of G
- Initialize G_w (working subgraph) by randomly setting each v to active/inactive and obtaining the induced subgraph
- Loop i=1 to N
 - Randomly pick a node v in V and toggle its state (new G_w)
 - Compute score for new subgraph s_i
 - If $s_i > s_{i-1}$ keep v toggled
 - Else keep v toggled with probability $p = e^{(s_i s_{i-1})/T_i}$
 - Output G_w

Additional heuristics

- Additional heuristics: Search for multiple (M) subnetworks simultaneously
- d_{min} (degree): remove low scoring neighbors for nodes with degree greater than d_{min}

Results

- Application to two networks
 - 362 protein-protein and protein-dna interactions in a yeast galactose utilization study
 - 7145 protein-protein and 317 protein-dna interactions
- Each condition was a single or double knockout of a gene in the galactose pathway
- Examine subnetworks in one condition (GAL80) (Figure 1)
- Examine subnetworks in multiple conditions (Figure 5)

Fig 1. Subnetworks identified in the 362 PPI, PDI using GAL80 knock out based z-score

Transcription factors are often not very differentially expressed

Analysis on small network with one perturbation (one condition)

Simulated annealing score convergence

Distribution of true and random subnetwork scores

Fig 5: Analysis on a larger network with multiple conditions

Result of applying another round of Simulated Annealing on subnetwork 1

Fig 6: Conditions in which specific subnetworks were active

Genes in the same subnetwork may be inversely correlated to each other

Take-away points

- A skeleton network based approach
 - Fixed network, but the node activity can change across conditions
- Key advantages over simple expression-based clustering
 - Find weakly expressed genes that are connected to genes that are highly expressed
 - More interpretative
 - Clustering may not connect two genes of opposite expression profiles
 - Can find subnetworks active for a subset of conditions
- Future extensions
 - Correcting for network topology
 - Inferring more attributes on the subnetworks
 - Better/different ways to find a subnetwork
